ABSTRACT

Rationale Evidence has suggested that exposure to environmental or microbial biodiversity in early life may impact subsequent lung function and allergic disease risk.

Objectives To investigate the influence of childhood living environment and biodiversity indicators on atopy, asthma and lung function in adulthood.

Methods and measurements The European Community Respiratory Health Survey II investigated ~10 201 participants aged 26–54 years from 14 countries, including participants' place of upbringing (farm, rural environment or inner city) before age 5 years. A 'biodiversity score' was created based on childhood exposure to cats, dogs, day care, bedroom sharing and older siblings. Associations with lung function, bronchial hyper-responsiveness (BHR), allergic sensitisation, asthma and rhinitis were analysed.

Main results As compared with a city upbringing, those with early-life farm exposure had less atopic sensitisation (adjusted OR 0.46, 95% CI 0.37 to 0.58), atopic BHR (0.54 (0.35 to 0.83)), atopic asthma (0.47 (0.28 to 0.81)) and atopic rhinitis (0.43 (0.32 to 0.57)), but not non-atopic outcomes. Less pronounced protective effects were observed for rural environment exposures. Women with a farm upbringing had higher FEV₁ (adjusted difference 110 mL (64 to 157)), independent of sensitisation and asthma. In an inner city environment, a higher biodiversity score was related to less allergic sensitisation.

Conclusions This is the first study to report beneficial effects of growing up on a farm on adult FEV₁. Our study confirmed the beneficial effects of early farm life on sensitisation, asthma and rhinitis, and found a similar association for BHR. In persons with an urban upbringing, a higher biodiversity score predicted less allergic sensitisation, but to a lesser magnitude than a childhood farm environment.

INTRODUCTION

A dramatic rise in asthma and allergic disease over recent decades has motivated extensive research into the aetiological factors responsible for these conditions. Various hypotheses have been put forth to explain this rise in allergic disease with respect to early-life exposures. Recent evidence has

Key messages

What is the key question?

- What is the relative impact of early-life farm exposure and other biodiversity proxies on adult lung function and bronchial hyper-responsiveness (BHR)?

What is the bottom line?

- This is the first study to report beneficial effects of growing up on a farm on adult FEV₁ and compare biodiversity proxy exposures for inner city participants to confirm the beneficial effects of early farm life on sensitisation, asthma, rhinitis and BHR.

Why read on?

- This study describes the associations between early-life farm or microbial proxy exposures and adult measures of clinical lung function, BHR and allergic disease to help define the role of microbial biodiversity and farm exposure on adult lung function outcomes.

indicated that the level of exposure to environmental or microbial biodiversity in early life may impact the subsequent risk of allergic outcomes. This hypothesis was initially generated by the observation of an inverse association between family size and hay fever, and has since been coined the 'hygiene hypothesis'.¹ This work has been subsequently expanded as the microbial hypothesis by observations on the links between exposure to farming environments and a reduction in allergic diseases. The 'farm effect' has been observed by a number of studies, the majority of which have focused on childhood farm exposure and disease onset in childhood, while fewer studies have investigated the impact of early-life exposures on adult disease phenotypes.^{2–3} Exposure to increased loads of microbes such as viral, bacterial and parasitic agents associated with farming environments has been proposed as contributing factors in this link, and previous studies have explored various routes of exposure associated with farm life

more thoroughly to investigate their relative contributions to this 'farm effect'.² Supporting this hypothesis, studies have also shown that endotoxin and fungal loads in farming homes are significantly higher than those in non-farming homes.^{4–8}

Following the interest in early life as a critical window for exposures that determine lifelong health and disease status, numerous studies have investigated the associations between childhood farm exposure and childhood allergic diseases. Systematic reviews synthesising considerable evidence from studies on early-life farm exposure and childhood disease outcomes have shown a decreased risk of asthma, wheeze and allergic disease associated with the 'farm effect'.^{3–9} However, fewer studies have analysed the impact of these childhood exposures on well-defined allergic adulthood outcomes or the potential persistence of the 'farm effect' into adult life.^{2–3–9} While the majority of existing research has investigated allergic outcomes including asthma, little work has been conducted on the association between early-life farm exposure and clinical measures of lung function in childhood, adolescence or adulthood.^{10–14} Findings in younger cohorts have been conflicting, with one study finding no improvements in spirometric measures related to the 'farm effect',¹² another study showing only higher FVC in children born on a farm¹⁴ and a third study finding a lower prevalence of bronchial hyper-responsiveness (BHR) in adolescents raised on a farm—a finding that was more distinct in girls.¹³ Although few articles have completely stratified this association by atopy to investigate this association among atopic and non-atopic groups, in a study on farming environments childhood health outcomes, Fuchs *et al*¹² found that farm exposure reduced risk of wheeze independent of atopic status and observed a statistically significant interaction between atopy and fractional exhaled nitric oxide, but not lung function or BHR. In this under-researched area, only one study has investigated the association between early-life farm exposure and adult lung function, finding no statistically significant results.¹¹ This study also found no association between a farm upbringing and risk of BHR. The only other study on this topic found decreased odds of adult BHR, with being 'born and raised' on a farm.¹⁰ Additionally, many studies on farming exposures and allergic disease outcomes rely on comparisons between categorised 'farming' and 'non-farming' communities, which may overlook the significance of intermediary rural exposures. This is an important distinction in the context that increasing urbanisation is linked to a higher prevalence of allergic disease.¹⁵ Moreover, the strength of the 'farming effect' is not often compared with the other associated early-life exposures related to environmental biodiversity such as pet keeping, older siblings, bedroom sharing and interactions with other children through day care or nursery school attendance.^{16–18} As such, it is currently unclear if exposures to an increased microbial load in an urban setting might approximate the effect of early-life farming exposure on allergic and respiratory disease outcomes.

In this article, we aim to add knowledge to these gaps in this field of research using the European Community Respiratory Health Survey (ECRHS), the largest international multicountry study of adult asthma, collected information on early childhood exposure to farming and place of upbringing. In addition, information was collected on other environmental exposures related to biodiversity and microbial load along with objective outcome measures of IgE-mediated sensitisation and lung function in adult life. Using these data, we aimed to investigate whether exposure to farming is related to adult allergic outcomes and lung function, and if so, whether any associations can be explained by microbial proxy markers.

METHODS

Study design and data collection tools

The methods of the ECRHS I have been fully described elsewhere.^{19–20} Briefly, in the ECRHS I, participating centres randomly selected samples of participants aged 20–44 years, from a total of 48 centres in 22 countries during 1991–1993. A sampling frame randomly selected 1500 men and women from pre-existing administrative boundaries with a population of at least 150 000 people, who were mailed a short postal questionnaire about asthma and asthma-like symptoms (stage 1). During stage 2, a random subsample, made up of roughly 20% of stage 1 respondents were invited to attend a local testing centre to complete a more detailed questionnaire administered by an interviewer and undergo skin prick and blood tests, assessment of lung function by spirometry and methacholine challenge testing. In addition, participants who were not in the random sample, but who reported current use of treatment for asthma, an asthma diagnosis, or who they had been woken with shortness of breath in the previous 12 months (symptomatic sample) were also invited to participate in stage 2.

The ECRHS II, conducted between 1998 and 2002, was a follow-up of the clinical participants included in the ECRHS I. Twenty-nine centres participated in this follow-up, where participants underwent a self-completed screening questionnaire, an administered clinical interview, lung function testing and serum IgE analysis. Clinical measures used in this analysis were collected during the ECRHS II follow-up. The data on early-life farm exposure and current respiratory symptoms that were used in this analysis were also collected in this survey. The detailed protocol can be found at <http://www.ecrhs.org>.

IgE measurements

Using the Pharmacia CAP System (Pharmacia Diagnostics AB, Uppsala, Sweden), total serum IgE and specific IgE levels to cat, house dust mite (*Dermatophagoides pteronyssinus*), mould *Cladosporium* and timothy grass were measured. Each sample was handled in a similar manner, with centrifugation and subsequent storage at –20°C until IgE analysis. The serum-level measurement range for total IgE was 2–2000 kU/L and 0.35–100 kUA/L for specific IgE.

Lung function

Lung function was assessed by spirometry, and the maximum FEV₁ and FVC were measured through a maximum of five acceptable tests.

BHR was measured by methacholine challenge testing. Methacholine was released via a Mefar dosimeter (Mefar, Bovezzo, Italy). Two minutes after each inhalation, FEV₁ was recorded, and the test was stopped when either a 20% fall in FEV₁ was achieved or the final methacholine dose had been given.

DEFINITIONS

Outcomes

BHR was defined by a fall of at least 20% in FEV₁ after the methacholine challenge test (accumulated dose 1 mg), and allergic sensitisation was characterised by at least one positive test to any specific allergen (≥ 0.35 kUA/L). Nasal allergies were determined by questionnaire with response to "Do you have any nasal allergies including 'hayfever'?" Current asthma was defined as BHR AND current wheeze OR the use of asthma medications in the last 12 months.²¹ Participants were classified as having current wheeze if they answered yes to the question

"Have you had wheezing or whistling at any time during the last 12 months?". Continuous measures of FEV₁, FVC and FEV₁/FVC were used in this analysis. The outcomes of asthma, rhinitis and BHR were stratified into allergic and non-allergic phenotypes based on the presence or absence of allergic sensitisation as defined above.

Primary exposure

For this analysis, participants were grouped by place of upbringing before the age of 5 years as reported in the ECRHS II follow-up survey. The question that collected the participant's childhood living environment was "What term describes the place you lived most of the time when you were under the age of 5 years? (a) farm (b) village in a rural area (c) small town (d) suburb of a city and (e) inner city". A three-level variable was used in the analysis with inner city, farm and a combined intermediary category of village, town or suburb. Similar findings and no statistically significant differences in outcomes were observed between the three intermediary groups when investigated individually. A small, but insignificant, difference was observed between suburb and village with suburbs having a lower benefit than village.

Other exposures

The 'proxy microbial load score' was calculated from answers to the following survey questions from the ECRHS II: (a) "At what age did you first attend a school, play school, day care or nursery?" (=1 if attended before age 5); (b) "Was there a dog/cat in your home during your first year of life OR when you were aged 1 to 4 years OR when you were aged 5–15 years?" (=1 for each affirmative answer) (c) "How many *other* children regularly slept in your bedroom before *you were five years old*?" (=1 if >0) and (d) "How many older brothers (or sisters) [do you have]?" (=1 if >0). The combined effect of daycare, pets, bedroom sharing and siblings in early life was examined together as the cumulative 'proxy microbial load score'. Individuals were given a score for the number of factors (0, 1, 2, 3, 4, 5 exposures).

Analytical methods

The significance of variation in baseline demographics by early-life residence was assessed with χ^2 tests or analysis of variance methods. Multiple and multinomial logistic regression analyses were performed to estimate adjusted ORs for the associations between childhood environment and clinical phenotypes while adjusting for relevant confounders. Multiple linear regression was performed to estimate the mean differences in lung function by differing early-life home environments while adjusting for possible confounders. A potential interaction between sex and childhood environment was investigated, and a stratified analysis was presented in the presence of a significant interaction. Sensitivity analyses were performed with adjustment for random and symptomatic sample membership and were consistent with the presented findings.

For all analyses, the following a priori confounders were included: age, sex, study centre, smoking status and family history of allergic disease. In addition, height² was determined to be an a priori confounder in the analysis of lung function data. A set of potential confounders were also explored during the analyses and were only included in the final model if the point estimate changed by more than 10%; these variables included maternal/paternal smoking, older siblings or bedroom sharing, early day care or nursery school attendance, early-life cat/dog ownership, socioeconomic status and weight in lung

function analyses. Potential heterogeneity of associations was studied across countries. A fixed-effect model was used to meta-analyse risk estimates when there was no significant heterogeneity based on the I^2 value (<50%) in order to compare risk estimates across participating countries.

A subgroup analysis, limited to those with inner city upbringing in the first 5 years, was performed using a score of microbial load and diversity exposures to evaluate whether the potential risk reduction in the outcomes is similar to any risk reduction related to exposure to farming.

All analyses were carried out using Stata V.12 (StataCorp, College Station, Texas).

RESULTS

Of the 10 201 participants with survey data for the question on childhood living environment, the majority reported living in a village in a rural area, small town or suburb of a city before the age of 5 years (63.9%). The percentage of inner city participants was 26.9% and the smallest group was those living on farms at 9.2%. Farm-exposed participants were significantly older at follow-up than those born in rural or inner city environments (table 1). The prevalence of exposure to dogs or cats during childhood, older siblings or bedroom sharing with older children was also higher in those who reported living on a farm environment before the age of 5 years. In addition, a family history of allergic disease was less prevalent in this group.

Allergic phenotypes

A lower prevalence of any allergic sensitisation ($p<0.001$), nasal symptoms ($p<0.001$) or BHR (0.002) was observed in participants reporting farm exposure before the age of 5 (table 2). Those who lived on a farm before the age of 5 years had a reduced risk (OR=0.46 95% CI 0.37 to 0.58) of adult atopy compared with those living in the inner city (table 2). Only a moderate reduction was observed in adults from a village/town/suburb. Stratification of nasal symptoms by sensitisation showed

*Additional adjustment: height² and weight.

BHR, bronchial hyper-responsiveness.

that the protective effect of the farming environment was limited to those with allergic nasal symptoms (OR= 0.43, 95% CI 0.32 to 0.57). Participants with early-life village, town or suburb, exposure did not have reduced risk of allergic nasal symptoms when compared with the inner city reference group. A similar pattern was observed for current allergic/non-allergic asthma in reference to place of upbringing, in which farm children experienced a significant reduction in the risk of allergic asthma by approximately 50%. On the other hand, the risk of current allergic asthma for those participants from a village, town or suburb was not significantly reduced when compared with the inner city reference group. A very similar pattern was also observed in the analysis of allergic/non-allergic BHR in relation to childhood environment.

Lung function

An interaction (p=0.03) was observed between gender and early-life home environment for FEV₁ (table 3), but not FEV₁/FVC ratio. After adjustment for a priori confounders and weight, females from a childhood farming environment experienced a significantly higher FEV₁ of approximately 110 mL

(95% CI 64 to 157). Slightly higher FEV₁/FVC values were observed for those who lived on a farm before the age of 5 years (0.60, p=0.036, table 2). However, this increase was found to be only modest after adjustment for maternal/paternal smoking and serious respiratory infections before the age of 5 years (p=0.115). No significant associations were observed with FEV₁/FVC categorised above and below 70%. Also, a higher FEV₁/FVC was not observed for village/town/suburb participants as compared with the inner city reference group.

Meta-analysis of the effects

No heterogeneity was seen between the associations of place of upbringing between countries for the outcome of allergic sensitisation (figure 1; I²=0%), while some heterogeneity was observed for the outcome of FEV₁ (figure 2; I²=44.8%). The pooled risk estimate for any sensitisation in the farming subgroup indicates a 53% (95% CI 0.36 to 0.59) reduction in the risk of sensitisation, while the village group had only 26% (95% CI 0.74 to 0.96) reduction when compared with individuals exposed to an inner city environment in early life. Higher FEV₁ levels were observed in females with a farm upbringing when

Figure 1 Fixed-effect meta-analysis for odds of any sensitisation by early-life home environment for each participating country. For each centre, the square gives the OR and the horizontal lines indicate 95% CI; the area of the square is proportional to the size of the study sample in each centre.

Figure 2 Random effects meta-analysis for mean difference in FEV₁ by country for farm compared with inner city in females. For each country, the square gives the weighted mean difference (WMD) and the horizontal lines indicate 95% CI; the area of the square is proportional to the size of the study sample in each country.

compared with those from an inner city (pooled mean=0.13 L, 95% CI 0.09 to 0.18).

Subgroup analyses

Descriptive statistics for each biodiversity score subgroup are displayed in table 4. Among those who lived in an inner city in

the first 5 years of life, a reduction in risk of any sensitisation was observed with increasing proxy microbial load score (trend $p=0.05$) (table 5). Similarly, for most outcomes, decreased odds of all allergic phenotypes were observed with increasing proxy microbial load score. However, as seen in table 5, early-life farming exposure was associated with a stronger reduction in

Statistically significant associations are given in bold.

Adjustment for age, sex, study centre, smoking and family history of allergic disease.

Additional adjustment: height and weight.

BHR, bronchial hyper-responsiveness.

the risk of sensitisation and allergic disease phenotypes than any level of proxy microbial exposure in the inner city.

DISCUSSION

In this international study, interestingly, a higher FEV₁ was observed only in females exposed to farming in the first 5 years of life independent of asthma and sensitisation, which to our knowledge has never been reported before. Furthermore, a protective effect of early-life farming exposure was observed on allergic sensitisation and, allergic phenotypes of nasal symptoms, asthma and BHR in adults, and while those raised on a

rural setting had some reduction in the risk of sensitisation, this was not as strong as seen for those raised on a farm. The association between farm exposure and sensitisation was consistent across all countries participating in this study while the effect on FEV₁ varied slightly across centres. Our findings on atopic sensitisation are consistent with an earlier ECRHS I analysis, conducted by Leynaert *et al.*,²² comparing farm versus non-farm participants, which found a reduced risk of atopic sensitisation in adulthood (crude odds ratio (ORc) 0.68, CI 95% 0.55 to 0.86) with living on a farm in childhood, but no associations were observed for risk of asthma (ORc 0.82; CI 95% 0.53 to

1.27) or wheeze (ORc 1.09; CI 95% 0.82 to 1.46). While early-life exposures in the inner city related to increasing proxies of microbial diversity were also shown to be associated with a decreased risk of sensitisation, this reduction of risk was not as large as with farm exposure alone.

Our analysis of proxy markers of increasing microbial exposures indicated that within an urban environment increased exposure to microbial load may reduce the risk of atopic disease but the magnitude of this effect does not match that observed with farm exposure. It is possible that prolonged contact with unique farm exposures such as livestock with extensive microbial diversity are unmatched by any exposure in the inner city. These findings further support the role of both load and diversity in environmental exposures in the development of allergic diseases, as proposed by the 'microbial diversity hypothesis'.^{23–27} It is also relevant to consider the possibility that proxy measures such as pet, daycare and crowding exposure can represent alternate factors or mechanisms that influence disease risk in addition to microbial biodiversity, which could potentially influence the estimates related to our biodiversity score. Additionally, selective avoidance of pets due to asthma or allergy could also influence inner city biodiversity scores, but would likely only play a small role in our estimates.²⁸ However, the overall findings from our analysis indicate that the diversity of early-life microbial exposures impacts disease outcomes later in adult life.

To date, the majority of work done on farm exposures has focused on the association between early-life farm contact and childhood allergic and respiratory disease outcomes, while very few studies have investigated the impact of early-farm contact on adult disease, and especially adult lung function.⁹ Our findings on the impact of farm exposure on lung function in women are novel. Differential response to a range of environmental exposures, such as microbial diversity, indoor environment and air pollution, might possibly contribute to this gender difference. Further, the actual exposures related to urban and rural environment might differ between men and women. It is possible that men work in different roles or for longer periods on a farm than females, to a point where their exposure levels become harmful instead of protective.²⁹ The social differences around standards of cleanliness for males and females could also impact the function of the hygiene hypothesis in relation to sex.³⁰ A sex-dependent functioning of the 'farm-effect' has been observed in children or adolescents in relation to the cumulative incidence of asthma and in adults with early-life farm exposure in relation to asthma, hay fever and atopy.^{29–31–32} In addition, gender differences have already been explored in relation to other environmental exposures and lung health and allergic disease outcomes. In a recent study by Mészáros *et al*,³³ exposure to home environmental tobacco smoke was found to increase the odds of current asthma only in males. Although the findings have been inconsistent, gender differences in response to air pollution have also been reported.^{34–35}

Gene–environment interactions have also been reported to play a crucial role in the association between farming and allergic/respiratory disease outcomes.^{36–37} It is suggested that those genetically susceptible may be at a higher risk of allergies and respiratory outcomes when exposed to farming, and such groups may select themselves out of farming populations. Interestingly, we observed those with farming exposure to have a lower prevalence of family history of allergies supporting this hypothesis.

Our recent review consolidated published literature showing significant interactions between CD14 gene polymorphisms and environmental microbial exposures with evidence of a protective effect on atopic disease in childhood.³⁷ Additional evidence has

also shown that the expression of toll-like receptor 2 (TLR2) genes may differ between farm and non-farm children, and it is believed that some TLRs may act through various pathways to modify the risk of allergic or respiratory diseases.^{38–39} It has also been hypothesised that polymorphisms in oxidative stress genes may play a role in gene–environment pollutant interactions that impact allergic and respiratory disease. However, investigations into the modification of respiratory disease risk through an altered oxidative stress response related to genetic variants of NAD(P)H:quinone acceptor oxidoreductase 1 (NQO1) and glutathione *S*-transferase (GST) genes, have shown mixed results.⁴⁰ The above discussion highlights that multiple genes may modify the role in the observed 'farm effect', and that future research into this field needs to take into account a number of potential environmental and genetic modifiers.

The strength of our study is that it is a well-powered multinational study on adult asthma and atopy, which collected various exposure data and objective clinical measures of atopic sensitisation and lung function by a standardised protocol. The potential limitations of this study are survey data on early-life exposures collected retrospectively and no objective measures of microbial diversity were available for comparison. Residual confounding, stemming from a wide variety of exposures associated with different living environments as mentioned above, may also be present in this analysis. These uncontrolled confounders may all contribute to the observed 'farm effect' in a unique way that should be teased out in future investigations. Finally, self-selection out of farm life for those with a family history of allergic disease can present bias. Although we have adjusted for a family history of allergic disease in our analyses, an amount of residual confounding may remain based on the severity of allergic disease symptoms. Without further exploration into early-life clinical outcomes such as lung function or age at disease onset, we are unable to completely determine whether effects on adult lung function or disease are arising as a result of the direct effect of childhood farm exposure on adult health or mediated through distinct effects on childhood disease. It is also possible that adult exposures, such as occupational or home environment, may modify the effect of early-life exposures on adult disease; however, no significant interactions were observed between early-life home environment and adult cleaning or agriculture occupations in these analyses.

CONCLUSIONS

Consistently across 14 countries, this analysis shows that early-life exposure to farm environments is protective against subsequent adult allergic diseases. The consistency of the findings across multicountry settings suggests that farming effects may be due to biological mechanisms rather than socio-cultural effects that would differ between countries. A novel finding was that women who grew up on a farm had higher lung function, and only mild heterogeneity was observed across 14 countries. Further work is necessary to explain gender differences. Our analysis further showed protective effects of markers of microbial diversity (pets, siblings, day care, etc) in persons with an inner city background, however, not as strong as protective effects related to farm upbringing. Future studies should aim to discern critical farm exposures that drive the association with sensitisation by exploring the microbial components of farm environments through molecular studies.
